

- 1 Materials that conduct electricity poorly or not at all are called **insulators**
- 2 Materials that conduct electricity are called **conductors**  
Insulators are able to collect charge as the charged particles cannot flow through them into other materials
- 3 Plastics such as acetate and polythene are able to collect charge because they are insulators.
- 4 Like charges will repel one another
- 5 Opposite charges will attract one another
- 6 You can charge an object by friction. This transfers electrons to one object and leaves one or both objects involved with an overall charge (positive or negative)
- 7 When charging by friction it is only electrons that are transferred (negative charge).
- 8 Charging by induction occurs when an object with an overall charge comes into close contact with a neutral object and causes an attraction of oppositely charged particles.
- 9 When there is a build up of charge, electrons flow in whichever direction removes the excess charge to become 'discharged' or 'earthed'. This may sometimes cause a spark.
- 10 Static electricity can be dangerous if too much charge builds up near flammable materials due to the spark.
- 11 This means objects in use around flammable materials need to be earthed e.g. petrol pumps
- 12 Static electricity can be used to distribute particles more evenly and this is used in paint sprayers for bikes and cars as well as crop sprayers
- 13 A charged object has a force field around it called an electric or electrostatic field. We can draw diagrams to represent the charge and strength of the fields.
- 14

- 17 The field is strongest where the lines are closer together and weakest where the lines are furthest apart. The field lines never cross.
- 18 We use arrows to show the direction a positively charged particle would move within the electrical field.
